

Chapter 2 – Relational models and relational algebra

Databases lectures

Dr Kai Höfig

Discussion/revision

- What is a database and what is the motivation to use it?
- What are the advantages of data storage in relations?
- What is meant by the schema architecture?
- What are the architectural patterns for databases and what are they good for?
- What is meant by a data model?

- 2.1 Relational data model
- 2.2 Integrity constraints
- 2.3 Relational algebra

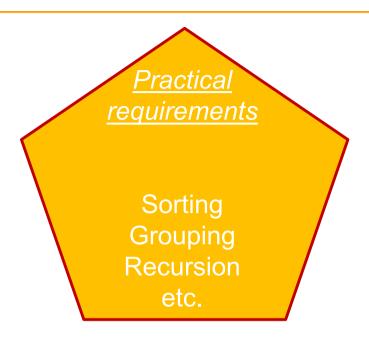

The relational data model

- Structure of the data:
 Data is stored in relations (tables)
- Operations on the data: 2 alternatives
 - Relational algebra: practically implemented in SQL language (Structured Query Language)
 - 2. Relational calculus: practically implemented in QBE (Query by Example) / QBC (Query by Criteria) language
- Integrity constraints: lots and lots! The most important:
 - 1. Key constraints
 - 2. Referential integrity = foreign key constraints
 - 3. Domain constraints (restrictions on values allowed for an attribute)
 - Integrity constraints can be formulated as conditions in relational algebra, relational calculus or SQL

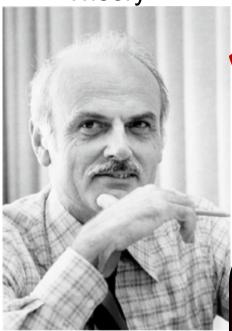

Relational algebra, calculus and languages

Relational algebra, calculus and languages

Theory

In the 1960s and 1970s, Codd created the relational model that forms the basis for relational databases, which are still a standard of database technology today. <u>Practical</u> requirements

Sorting
Grouping
Recursion
etc.

Relational algebra
Tuple relational calculus

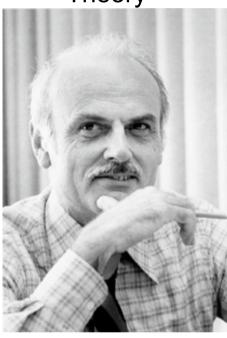

Domain relational calculus

Logical foundation

Relational algebra, calculus and languages

Theory

In the 1960s and 1970s, Codd created the relational model that forms the basis for relational databases, which are still a standard of database technology today. <u>Practical</u> requirements

Sorting
Grouping
Recursion
etc.

Relational algebra Tuple relational calculus

Domain relational calculus

Logical foundation

Without understanding the logical foundation, we interact with an unknown communication partner using the database languages

Practicable database languages

SQL

QBE

Practice

Relational algebra, calculus and languages - script

- Without a logical foundation, it is not possible to design good languages for practice.
- Why do we need the relational algebra and two forms of calculus?
 - Tuple relational calculus is the basis of SQL → important for understanding SQL
 - Domain relational calculus is the basis of QBE (and also QBC) → important for understanding QBE
 - Calculuses are declarative, i.e. the calculation sequence is not visible, i.e.
 - Easier to use than procedural instructions user does not need to know <u>how</u> the DBMS calculates the result.
 - DBMS has freedom with processing, so it can choose one that is as efficient as possible.
 - Algebra is procedural, i.e. it specifies the processing sequence ("from inside to outside").
 - There are laws for the transformation of algebra expressions.
 - DBMS translates the SQL query (=tuple relational calculus) into an algebra expression, optimises it (query optimiser) and executes it.
 - This "execution plan" is used by the DB administrator to optimise the DB (e.g. by means of index structures).

WINES

WineID	Name	Colour	Vintage	Vineyard

Representation of relations and terms

Representation

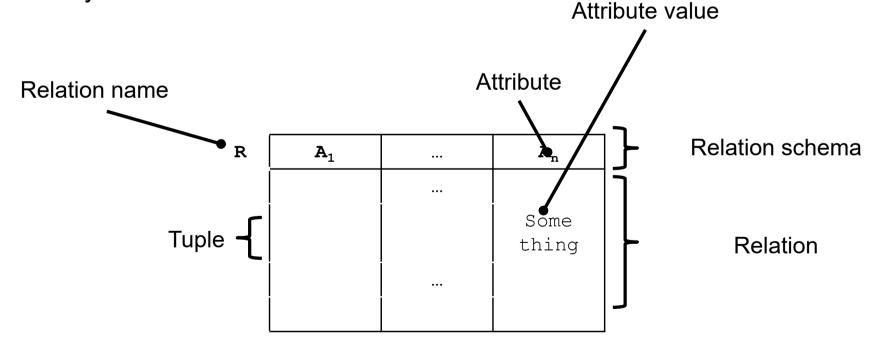

First row: relation schema

Other entries in the table: relation

One row of the table: tuple

A column heading: attribute

One entry: attribute value

Definition of the relational data model (1)

- In the relational data model, we only have the relational schema for structural modelling.
- $R=\{A_1,...,A_k\}$ is a **relational schema** with the identifier R via the attributes $A_1,...,A_k$ to the value ranges $D_1,...,D_s$ with $dom: \{A_1,...,A_k\} \rightarrow \{D_1,...,D_s\}, s \ge 1$, the value range function.

- A relational database schema is a finite non-empty set $S = \{R_1(\alpha_1),...,R_m(\alpha_m)\}$ of relational schemas via subsets of a common attribute set $\alpha = \alpha_1,...,\alpha_m$
- Thereby, all identifiers of relations are different in pairs and different from all attribute identifiers.

Definition of the relational data model (1)

- In the relational data model, we only have the relational schema for structural modelling.
- $R = \{A_1, ..., A_k\}$ is a **relational schema** with the identifier R via the attributes $A_1, ..., A_k$ to the value ranges $D_1, ..., D_s$ with $dom: \{A_1, ..., A_k\} \rightarrow \{D_1, ..., D_s\}, s \ge 1$, the value range function.
 - Example:

```
PRODUCER = { Vineyard, Growing_area, Region } with dom(Vineyard) = string, dom(Growing_area) = string, <math>dom(Region) = string
```

- A relational database schema is a finite non-empty set $S = \{R_1(\alpha_1),...,R_m(\alpha_m)\}$ of relational schemas via subsets of a common attribute set $\alpha = \alpha_1,...,\alpha_m$
- Thereby, all identifiers of relations are different in pairs and different from all attribute identifiers.

Definition of the relational data model (2)

- A relation r via a relational schema $R = \{A_1, ..., A_k\}$ in short r(R) is a finite set of tuples that map each attribute A_i to a value from $dom(A_i)$.
 - Example: a potential relation r via the relational schema PRODUCER is

- A database via a database schema $S = R_1(\alpha_1),..., R_m(\alpha_m)$ is a set of relations $d:=\{r_1,...,r_p\}$ where each relation r_i is defined via the relational schema $R_i: R_i(R_i)$
- A relation r ∈ d is referred to as a base relation
 - Example: our database schema WineDB contains exactly 2 base relations, which we

Definition of the relational data model (2)

- A relation r via a relational schema $R = \{A_1, ..., A_k\}$ in short r(R) is a finite set of tuples that map each attribute A_i to a value from $dom(A_i)$.
 - Example: a potential relation r via the relational schema PRODUCER is with

```
t_2(Vineyard)='Helena' t_2(Growing_area)='Napa Valley' t_2(Region)='California' t_3(Vineyard)='Müller' t_3(Growing_area)='Rheingau' t_3(Region)='Hesse'
```

- A database via a database schema $S = R_1(\alpha_1),..., R_m(\alpha_m)$ is a set of relations $d:=\{r_1,...,r_p\}$ where each relation r_i is defined via the relational schema $R_i: R_i(R_i)$
- A relation $r \in d$ is referred to as a base relation
 - Example: Our database schema WineDB contains 4 base relations, which we formally refer to as r1(WINES), r2(PRODUCER), r3(RECOMMENDATION), r4(WINE_LIST)

Key property:

One or more attributes identify uniquely stored tuples

Key property:

One or more attributes identify uniquely stored tuples

Example: Attribute Vineyard for table PRODUCER

PRODUCER

Vineyard	Growing_area	Region
Creek	Barossa Valley	South Australia
Helena	Napa Valley	California
Chateau La Rose	Saint-Emilion	Bordeaux
Chateau La Pointe	Pomerol	Bordeaux
Müller	Rheingau	Hesse
Bighorn —	Napa Valley	California

Key constraint: There are no 2 tuples in PRODUCER with the same value of Vineyard

Key property:

One or more attributes identify uniquely stored tuples

Example: Attribute Vineyard for table PRODUCER

PRODUCER

Vineyard	Growing_area	Region
Creek	Barossa Valley	South Australia
Helena	Napa Valley	California
Chateau La Rose	Saint-Emilion	Bordeaux
Chateau La Pointe	Pomerol	Bordeaux
Müller	Rheingau	Hesse
Bighorn —	Napa Valley	California

Note

- Attribute combinations can also be keys
- A table can have multiple keys
- When the DB is designed, a key is selected as the primary key
- Keys are generally marked by underlining

Key constraint: There are no 2 tuples in PRODUCER with the same value of Vineyard

Important integrity constraints in RM: Referential integrity

WINES

WineID	Name	Colour	Vintage	Vineyard →	PRODUCER

Query operations on tables

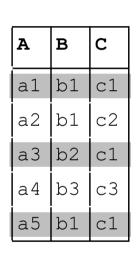

- Relational algebra: set of basic operations on relations to compute new (result) relations
 - can be combined in any way
 - thereby create an algebra for "calculating with tables"
- Revision from mathematics:
 algebra = value range + operations defined on these
- Here
 - value range = contents of the database = tables
 - operations = functions for calculating new tables

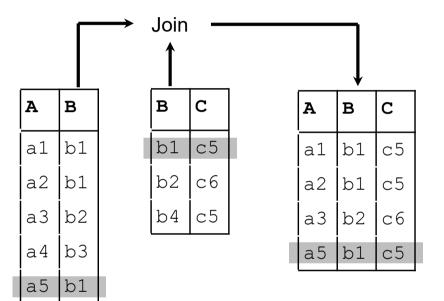

Relational algebra: overview

Three main operations: Selection, Projection, Join

Projection

Selection

Join

Projection π definition

- Projection π (Pi): selection of columns by specifying an attribute list
- The projection removes duplicate tuples (set semantics)
- Syntax:

$$\pi_{\text{Attribute set}}$$
 (Relation) or []

Example:

$$\pi_A(R)$$
 or $R[A]$

Semantics

$$\pi_{X}(r) := \{ t(X) \mid t \in r \}$$

for r(R) and $X \subseteq R$ attribute set in R

• Property for $Y \subseteq X \subseteq R$: $\pi_Y(\pi_X(r)) = \pi_Y(r)$

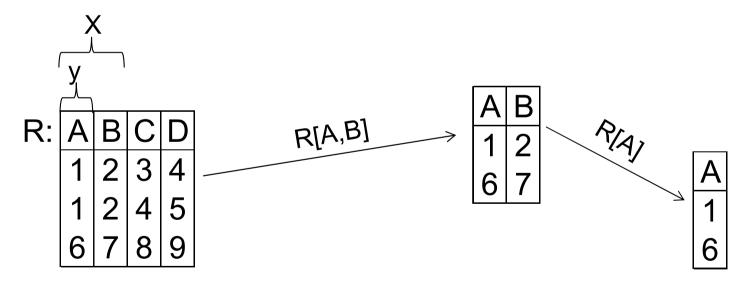

Semantics

$$\pi_X(r) := \{ t(X) \mid t \in r \}$$

for r(R) and $X \subseteq R$ attribute set in R

• Property for $Y \subseteq X \subseteq R$: $\pi_Y(\pi_X(r)) = \pi_Y(r)$

Note: π removes duplicates (set semantics)

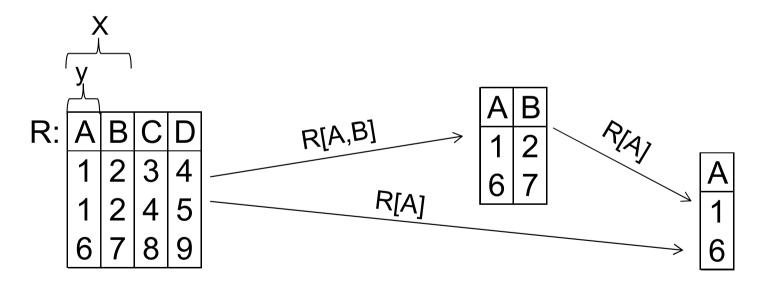

Semantics

$$\pi_X(r) := \{ t(X) \mid t \in r \}$$

for r(R) and $X \subseteq R$ attribute set in R

• Property for $Y \subseteq X \subseteq R$: $\pi_Y(\pi_X(r)) = \pi_Y(r)$

Note: π removes duplicates (set semantics)

Projection: further examples

Relation

PRODUCER

Vineyard	Growing_area	Region
Creek	Barossa Valley	South Australia
Helena	Napa Valley	California
Chateau La Rose	Saint-Emilion	Bordeaux
Chateau La Pointe	Pomerol	Bordeaux
Müller	Rheingau	Hesse
Bighorn	Napa Valley	California

• π_{Region} (PRODUCER)

Region South Australia California Bordeaux Hesse

$\pi_{\texttt{Growing_area,Region}}(\texttt{PRODUCER})$

Growing_area	Region	
Barossa Valley	South Australia	
Napa Valley	California	
Saint-Emilion	Bordeaux	
Pomerol	Bordeaux	
Rheingau	Hesse	

Selection of definition

- <u>Selection</u> σ (<u>Sigma</u>): selection of rows of a table based on a selection predicate
- Syntax: $\sigma_{\text{<Constraint>}}(\text{<Relation>}) \text{ or <Relation>}[\text{<Constraint>}]$
- Semantics (for $A \in R$)

$$\sigma_{A=a}(r) := \{ t \in r \mid t(A) = a \}$$

Example:

$$\sigma_{A=1}(R)$$
 or R[A=1]

Selection conditions

Constant selection

Attribute θ Constant

Boolean predicate θ is = or \neq , for linear value ranges also \leq , <, \geq or >

Attribute selection

Attribute₁
$$\theta$$
 Attribute₂

Logical linking of multiple constant selections or attribute selections with ∧,
 ∨ or ¬.

Selection: Laws for transformation - commutativity

Commutativity

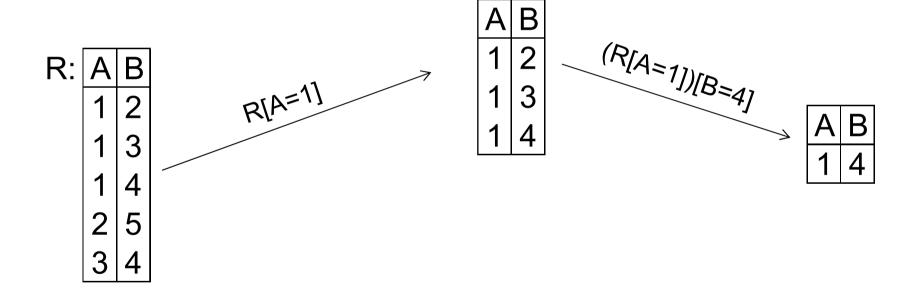

$$\sigma_{A=a}(\sigma_{B=b}(r)) = \sigma_{B=b}(\sigma_{A=a}(r))$$

Selection: Laws for transformation - commutativity

Commutativity

$$\sigma_{A=a}(\sigma_{B=b}(r)) = \sigma_{B=b}(\sigma_{A=a}(r))$$

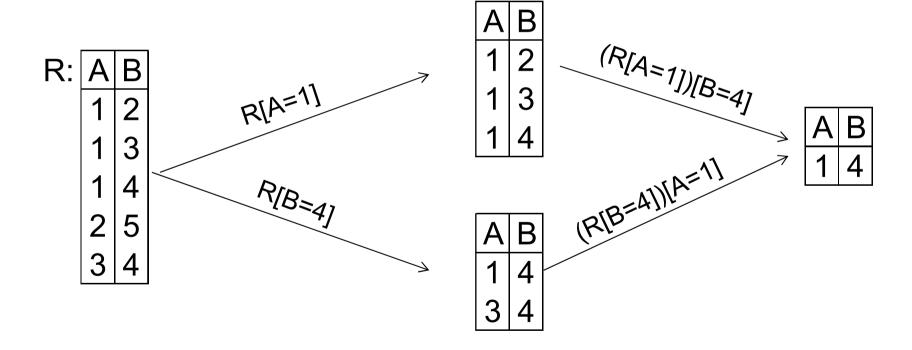

Selection: Laws for transformation - commutativity

Commutativity

$$\sigma_{A=a}(\sigma_{B=b}(r)) = \sigma_{B=b}(\sigma_{A=a}(r))$$

Selection: Laws for transformation - transposition

• If $A \in X$, $X \subseteq R$

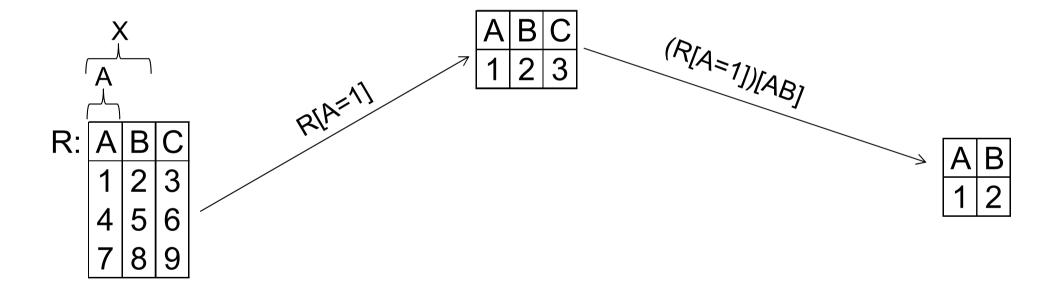

$$\pi_X(\sigma_{A=a}(r)) = \sigma_{A=a}(\pi_X(r))$$

Selection: Laws for transformation - transposition

• If $A \in X$, $X \subseteq R$

$$\pi_X(\sigma_{A=a}(r)) = \sigma_{A=a}(\pi_X(r))$$

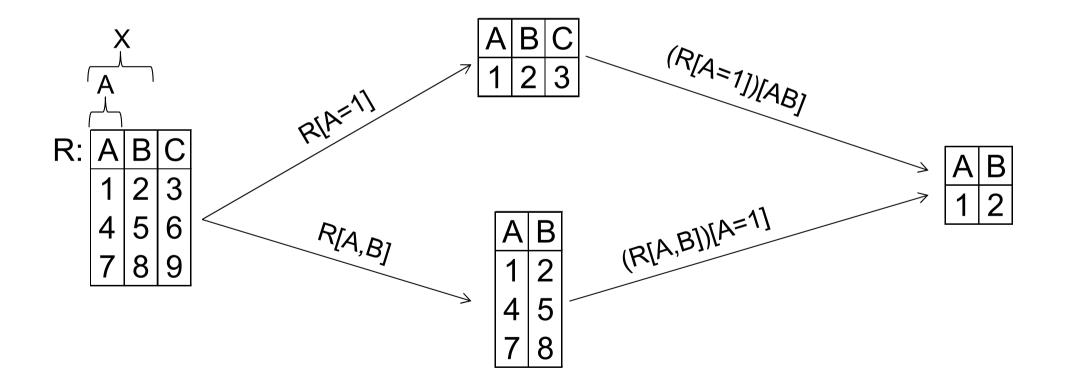

Selection: Laws for transformation - transposition

• If $A \in X$, $X \subseteq R$

$$\pi_X(\sigma_{A=a}(r)) = \sigma_{A=a}(\pi_X(r))$$

Cross product ×

- Cross product × (Cartesian product, cross join): links two tables by combining each tuple of the first with each tuple of the second.
 - Be careful: result for tables with n or m tuples has n*m tuples!
- Syntax: <Relation1> × <Relation2>
- Semantics: $R \times S := \{ x_1..x_n..x_{n+m} | R(x_1,...,x_n) \land S(x_{n+1},...,x_{n+m}) \}$

Cross product ×

- Cross product × (Cartesian product, cross join): links two tables by combining each tuple of the first with each tuple of the second.
 - Be careful: result for tables with n or m tuples has n*m tuples!
- Syntax: <Relation1> × <Relation2>
- Semantics: $R \times S := \{ x_1...x_n...x_{n+m} \mid R(x_1,...,x_n) \land S(x_{n+1},...,x_{n+m}) \}$
- Example:

* Attributes with the same name are renamed

$Cross\ product \times example$

Example:

WINES × BOTTLE

			···		•••	

- - Tuples that do not find a partner (dangling tuples) are eliminated.
- Syntax: <Relation1> ▷
- Semantics for A attributes of R, C attributes of S and B attributes with intersection

$$R \triangleright \triangleleft S := {}_{\pi A1,...,Am,R.B1,...,R.Bk,S1,...,Sn}(\sigma_{R.B1=S.B1}, \dots, \sigma_{R.Bk=S.Bk}(R \times S))$$

Example:

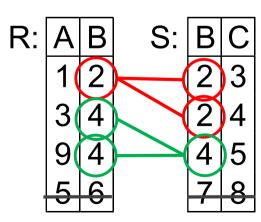

₹:	Α	В	S:	В	\mathbf{O}
		2		2	3
	3	4		2 4	4
	9	4		4	5
	5	6		7	8

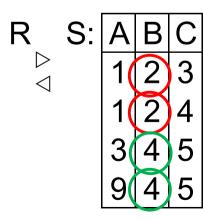

- Natural join: >links tables via columns of the same name, by merging two tuples if they have the same values there
 - Tuples that do not find a partner (dangling tuples) are eliminated.
- Syntax: <Relation1> ▷
- Semantics for A attributes of R, C attributes of S and B attributes with intersection

$$R \triangleright \triangleleft S := {}_{\pi A1,..,Am,R.B1,..,R.Bk,S1,..,Sn}(\sigma_{R.B1=S.B1}, \dots, \sigma_{R.Bk=S.Bk}(R \times S))$$

Example:

Natural join example ⊳⊲

Example:

WINES ⊳⊲ PRODUCER

Natural join example ⊳⊲

Example:

WINES ▷< PRODUCER

WineID	Name		Vineyard	Growing_area	Region
1042	La Rose GrandCru		Chateau La Rose	Saint-Emilion	Bordeaux
2168	Creek Shiraz		Creek	Barossa Valley	South Australia
3456	Zinfandel		Helena	Napa Valley	California
2171	Pinot Noir		Creek	Barossa Valley	South Australia
3478	Pinot Noir		Helena	Napa Valley	California
4711	Riesling Reserve	ļ	Müller	Rheingau	Hesse
4961	Chardonnay	ļ	Bighorn	Napa Valley	California

The "Château La Pointe" vineyard has disappeared from the result

Join: Laws for transformation

$$R \triangleright \triangleleft S := {}_{\pi A1,..,Am,R.B1,..,R.Bk,S1,..,Sn}(\sigma_{R.B1=S.B1} \land ... \land R.Bk=S.Bk}(R \times S))$$

- From $R_1 \cap R_2 = \{\}$ follows $r_1 \triangleright \triangleleft r_2 = r_1 \times r_2$. If there are no attributes with intersection, the condition σ of the definition of the natural join is removed.
- Commutativity: $R_1 \triangleright \triangleleft r_2 = r_2 \triangleright \triangleleft r_1$ The conditions and projections in the definition are commutative.
- Associativity: $(r_1 \triangleright \triangleleft r_2) \triangleright \triangleleft r_3 = r_1 \triangleright \triangleleft (r_2 \triangleright \triangleleft r_3)$

therefore allowed: $\triangleright \triangleleft p_{i=1} r_i$

Renaming B

- Renaming β (Beta): adjusting and renaming attributes
- Syntax:

$$\beta_{\text{}\leftarrow \text{}}(\text{})$$
 or [Source attribute \rightarrow Target attribute]

Semantics

$$\beta_{B \leftarrow A}(r) := \{ t' \mid \exists t \in r : t'(R-A) = t(R-A) \land t'(B) = t(A) \}$$

Renaming B

- Renaming β (Beta): adjusting and renaming attributes
- Syntax:

$$\beta_{\text{}\leftarrow \text{}}(\text{})$$
 or [Source attribute \rightarrow Target attribute]

Semantics

$$\beta_{B \leftarrow A}(r) := \{ t' \mid \exists t \in r : t'(R-A) = t(R-A) \land t'(B) = t(A) \}$$

Example:

R:	Α	В	C	D	$R[A \rightarrow X]$:	X
	1	2	3	4		1
		7				6

- Now possible by renaming
 - joins, where Cartesian products were previously carried out (different attributes are named the same),
 - Cartesian products, where previously joins were carried out (same attributes are named differently),
 - set operations

Renaming example

How can the operations presented so far be used to create a table with the people, their children and their grandchildren?

R:	Person	Kind
	Karl der Große	Ludwig der Fromme
	Ludwig der Fromme	Lothar der I
	Ludwig der Fromme	Karl II der Kahle
	Lothar der I	Ludwig der II

Renaming example

How can the operations presented so far be used to create a table with the people, their children and their grandchildren?

R:	Person	Kind
	Karl der Große	Ludwig der Fromme
	Ludwig der Fromme	Lothar der I
	Ludwig der Fromme	Karl II der Kahle
	Lothar der I	Ludwig der II

R ':	Person	Kind	Enkel
	Karl der Große	Ludwig der Fromme	Lothar der I
	Karl der Große	Ludwig der Fromme	Karl II der Kahle
	Ludwig der Fromme	Lothar der I	Ludwig der II

• R $\triangleright \triangleleft$ ($\beta_{Child \leftarrow Person}(\beta_{Grandchild \leftarrow Child}(R))$) or R $\triangleright \triangleleft$ ((R[Child \rightarrow Grandchild])[Person \rightarrow Child])

Calculation of the cross product from natural join

- Natural join degenerates to a cross product if no common attributes exist
- Forcing by renaming: $R_1(A, B, C)$ and $R_2(C, D)$

Calculation of the cross product from natural join

- Natural join degenerates to a cross product if no common attributes exist
- Forcing by renaming: $R_1(A, B, C)$ and $R_2(C, D)$

$$R_1 \times R_2 \equiv R_1 \triangleright \triangleleft \beta_{E \leftarrow C}(R_2)$$

Cross product + selection simulates natural ioin

Calculation of the cross product from natural join

- Natural join degenerates to a cross product if no common attributes exist
- Forcing by renaming: $R_1(A, B, C)$ and $R_2(C, D)$

$$R_1 \times R_2 \equiv R_1 \triangleright \triangleleft \beta_{E \leftarrow C}(R_2)$$

Cross product + selection simulates natural join

$$R_1 \triangleright \triangleleft \qquad R_2 \equiv \sigma_{R_1.C=R_2.C}(R_1 \times R_2)$$

- Which structural elements of the relational data model are we familiar with?
- What relational algebra operations are there?

- Combinations of operations are possible
- Example

```
\pi_{\text{Name,Colour,Vineyard}}(\sigma_{\text{Vintage}>2000}(\text{WINES})) > \subset \sigma_{\text{Region}=\text{``California''}}(\text{PRODUCER}))
```

- Combinations of operations are possible
- Example

$$\pi_{\text{Name,Colour,Vineyard}}(\sigma_{\text{Vintage}>2000}(\text{WINES})) \supset \sigma_{\text{Region="California"}}(\text{PRODUCER}))$$

(WINES[Vintage>2000]

▷ □ PRODUCER[Region="California"])[Name, Colour, Vineyard]

results in

Name	Colour	Vineyard
Zinfandel	Red	Helena
Chardonnay	White	Bighorn

- Using brackets for the expression is important!
- Example

```
\pi_{\text{Name,Colour,Vineyard}}(\sigma_{\text{Vintage}>2000}(\text{WINES})) \triangleright \lhd \sigma_{\text{Region="California"}}(\text{PRODUCER})
```

(WINES[Vintage>2000])[Name,Colour,Vineyard] ▷< PRODUCER[Region= "California"]

- Using brackets for the expression is important!
- Example

$$\pi_{\text{Name,Colour,Vineyard}}(\sigma_{\text{Vintage}>2000}(\text{WINES})) \triangleright \lhd \sigma_{\text{Region="California"}}(\text{PRODUCER})$$

(WINES[Vintage>2000])[Name,Colour,Vineyard] ▷< PRODUCER[Region= "California"]

results in

Name	Colour	Vineyard	Growing_area	Region
Zinfandel	Red	Helena	Napa Valley	California
Chardonnay	White	Bighorn	Napa Valley	California

Set operations: union

- Union $r_1 \cup r_2$ of two relations r_1 and r_2 : collects the tuple sets of two relations under a common schema
- Attribute sets of both relations must be identical
- Semantics: for $r_1(R)$ and $r_2(R)$

$$r_1 \cup r_2 := \{ t \mid t \in r_1 \lor t \in r_2 \}$$

Example:

R:				Α	В	С	R ∪ S:	Α	В	С
	1	2	3	4	5	6		1	2	3
	4	5	6	7	8	9		4	5	6
								7	8	9

Pinot Noir

Set operations: intersection

- Intersection $r_1 \cap r_2$: returns the tuples that are common to both relations
- Semantics: for $r_1(R)$ and $r_2(R)$

$$r_1 \cap r_2 := \{ t \mid t \in r_1 \land t \in r_2 \}$$

Example:

• Intersection \cap due to $r_1 \cap r_2 = r_1 - (r_1 - r_2)$ is superfluous

Example intersection

• WINE_LIST $\cap \beta_{Name \leftarrow Wine}$ (RECOMMENDATION)

Example intersection

• WINE_LIST $\cap \beta_{Name \leftarrow Wine}$ (RECOMMENDATION) results in

Name

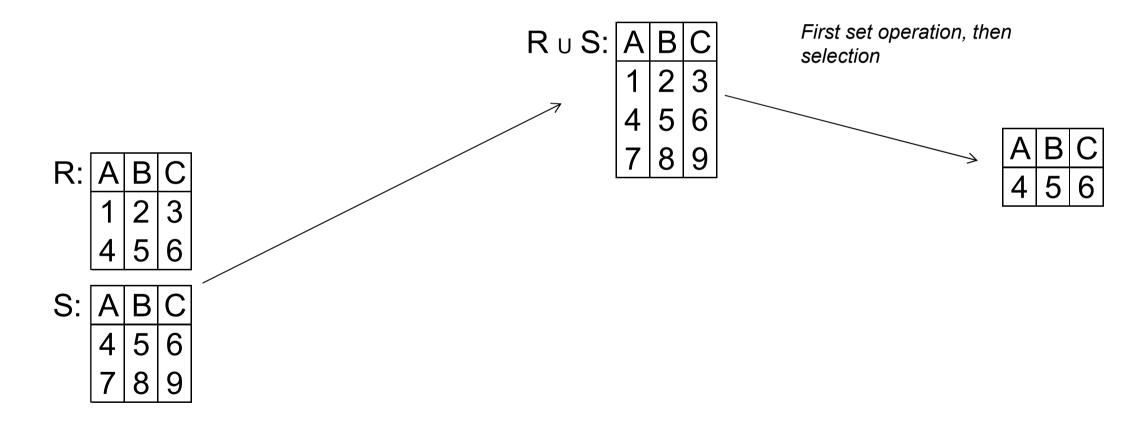

La Rose Grand Cru Riesling Reserve

Set operations: Laws for transformation

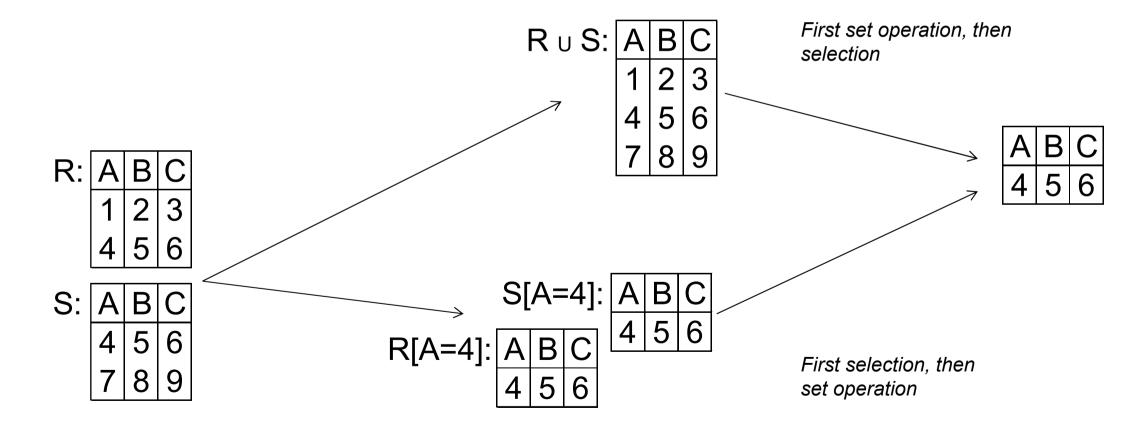

$$\sigma_{A=a}(r \cup s) = \sigma_{A=a}(r) \cup \sigma_{A=a}(s)$$

Set operations: Laws for transformation

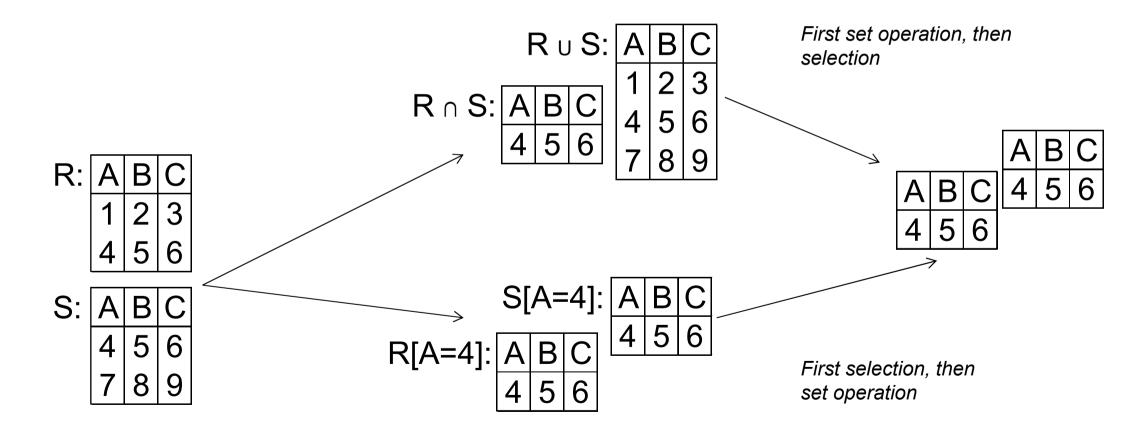

$$\sigma_{A=a}(r \cup s) = \sigma_{A=a}(r) \cup \sigma_{A=a}(s)$$

Set operations: Laws for transformation

$$\sigma_{A=a}(r \cup s) = \sigma_{A=a}(r) \cup \sigma_{A=a}(s)$$

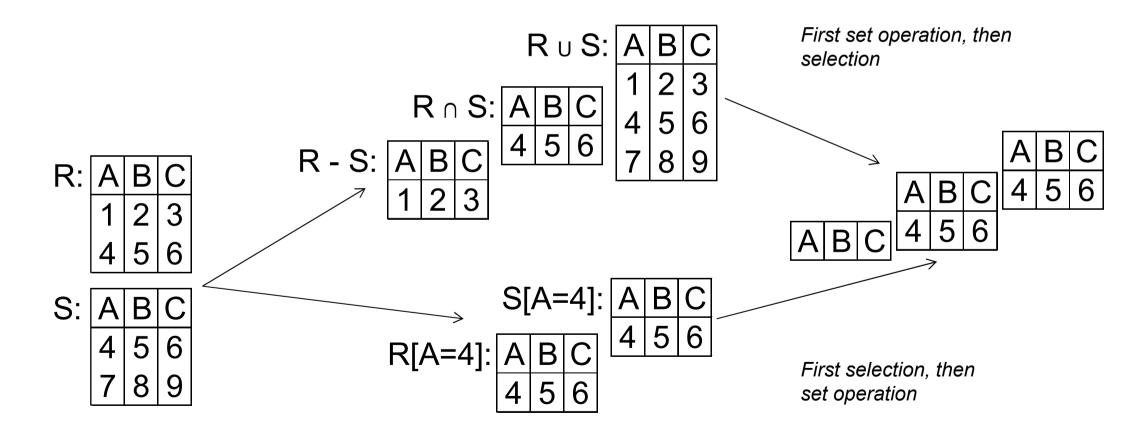

Datenbanken

Set operations: Laws for transformation

$$\sigma_{A=a}(r \cup s) = \sigma_{A=a}(r) \cup \sigma_{A=a}(s)$$

Relational algebra

- Hide columns: Projection π
- Search for rows: Selection σ
- ◆ Link tables: Join >< and cross product ×</p>
- ◆ Unify tables: Union ∪
- Subtract tables from each other: Difference and intersection \(\cap \)
- Rename columns: Rename β (important for $\triangleright \triangleleft$ and \cup , -)

Application example

All bicycles that are produced in Germany and 22" in size.

Bike (B)

BName	BManufacturer	BSize
Stereo 150	Cube	22
Balance bike	Puky	8

Manufacturer (M)

MName	MCountry
Bicicomp	49
Puky	49
Yeti Cycles	1

Country (C)

CCode	CName
49	DE
1	USA

With cross product:

$$\pi_{FName}(\sigma \underset{\land CName=DE}{\underset{\land CName=DE}{\underset{\land BManufacturer=MName}{\land MCountry=CCode}}} (B \times M \times C))$$

With natural join:

$$\pi_{FName}(\sigma_{\begin{subarray}{c}BSize=22\\ \land \cite{CName}=DE\end{subarray}}(\beta_{MName\leftarrow BManufacturer}(B)\bowtie\beta_{CCode\leftarrow MCounty}(M)\bowtie C))$$

Independence and completeness

- A query language is called relationally complete if every relational algebra operation in the language can be executed by (one or more) commands
- There is a minimal set of operations within the relational algebra from which all other operations can be composed: $\Omega = \pi$, σ , $\triangleright \triangleleft$, β , \cup and -
 - Ω is independent: no operator can be omitted without losing completeness
 - Other independent, complete sets: replace ▷< and β with ×
- Thus: it is sufficient to show that all operations from Ω can be expressed in a
 query language to show that this is relationally complete
- SQL is relationally complete!

- Which structural elements of the relational data model are we familiar with?
- What relational algebra operations are there?
- Which set of relational algebra operations is relationally complete and independent? Why is this important?
- Which integrity constraints do we know from the relational data model?
